Fourier Transform Infra Red (FTIR) and Broadband Dielectric Spectroscopy (BDS) are combined to study both the intra- and inter-molecular dynamics of two isomers of glass forming fucose, far below and above the calorimetric glass transition temperature, \( T_g \). It is shown that the various IR-active vibrations exhibit in their spectral position and oscillator strength quite different temperature dependencies, proving their specific signature in the course of densification and glass formation. The coupling between intra- and inter molecular dynamics is exemplified by distinct changes in IR active ring vibrations far above the calorimetric glass transition temperature at about \( 1.16T_g \), where the dynamic glass transition (\( \alpha \) relaxation) and the secondary \( \beta \) relaxation merge. For physically annealed samples it is demonstrated that upon aging the different moieties show characteristic features as well, proving the necessity of atomistic descriptions beyond coarse-grained models.

1 Introduction

The dynamic glass transition (DGT) is one of the most investigated phenomena in condensed matter physics,1-5 and its underlying mechanism is still a matter of hot debate. This is reflected in the large number of experimental studies on this issue, e.g. by dynamical mechanical thermal analysis, nuclear magnetic resonance (NMR), temperature modulated differential scanning calorimetry, light or particle scattering, photon correlation spectroscopy and many more.6-9 Furthermore, there is a multitude of different, controversially discussed models, such as the Adam-Gibbs model with its cooperatively rearranging regions, free volume theory, mode coupling theory, as well as the random first order transition or the two order parameter model.10-13 All these models rely on different assumptions concerning the inter-molecular interactions, but none takes into account the intra-molecular interactions and how these may depend on molecular structure and temperature. But, recent NMR-studies reveal changes in the intra-molecular mobility in the course of vitrification.14-16 The importance of this mobility in the sense of (sub-) molecularly specific contributions to the DGT has been recently proven by a combination of Broadband Dielectric Spectroscopy (BDS) and Fourier Transform Infrared Spectroscopy (FTIR).17-19 This combined approach, measuring the inter- and intra-molecular interactions by the two respective techniques, is utilized here to study the glass formation of two isomeric forms of fucose, a saccharide with pharmaceutical applications.20 Both methods (for a review see the monographs of Kremer and Schönhals21 and Griffiths and Haseth22) have been used separately before to investigate similar glass forming sugars of different molecular weights. Changes in temperature (\( T \)), pressure, chemical structure and purity have been studied by BDS by several authors revealing a strong impact of all four on the emerging dynamics.23-31 Using FTIR Imamura et al.32 and Wolkers et al.33,34 found a remarkable sensitivity to the glass transition of the spectral positions of hydroxyl group vibrations. In the following we present the temperature dependence of fucose in a wide range around the glass transition temperature, \( T_g \), and time dependent (aging) measurements for \( T < T_g \). Insights into the molecular scale are gained by analysis of FTIR active vibrations of all molecular moieties and detailed comparison with the dynamic properties obtained by BDS.

2 Experimental

The chemical structure of \( \delta \) - and \( \iota \)-fucose is presented in Fig. 1, including assignments of FTIR bands as well as dielectric \( \alpha \), \( \beta \) and \( \gamma \) relaxations. Both samples are supplied by Sigma Aldrich...
with purity higher than 99% in an anhydrous, crystalline state. The samples are first melted at $T = 418$ K between stainless steel electrodes before dielectric measurements are performed starting from $T = 335$ K to $T = 143$ K in steps of 4 K and at frequencies ranging from $10^2 < f < 10^7$ Hz by employing a Novocontrol Alpha analyzer accomplished with a Quatro temperature controller (temperature stability: 0.1 K). Samples for FTIR measurements are prepared in the same manner as described above but kept between KBr windows instead of metal electrodes. IR spectra are collected at each 2 K between $T = 393$ K and $253$ K in the range of 700 to 6000 cm$^{-1}$ and a spectral resolution of 2 cm$^{-1}$ using a Bio-Rad FTS-6000 spectrometer. The temperature is controlled using a Linkam THMS 600 heating stage with an accuracy of about 0.2 K and a net heating rate of about 1.4 K min$^{-1}$. No indications of thermal or chemical degradation (caramelization) are observed in the FTIR spectra collected upon melting of D- and L-fucose, nor are any changes in colour observable. For time dependent (aging) experiments the same experimental setups and samples are used. To allow observation of large effects during physical aging, we equilibrate the samples at 418 K for about 5 min and cool them afterwards at a rate of $33$ K min$^{-1}$ (FTIR) or 10 K min$^{-1}$ (BDS) to the designated temperature before starting the measurements. BDS experiments are performed at $T = 273$ K, 278 K and $283$ K where the $\beta$ and $\gamma$ processes are in the accessible frequency range. Effects of aging that can be seen with FTIR are subtle and, therefore, we chose aging temperatures closer to $T_{g}$ where the effects are more pronounced (eight measurements in between 287 and 300 K and just one at 273 K).

By use of the Gaussian$^{15}$ and the orca$^{16}$ software package the geometry of all forms$^{1}$ of fucose is optimized in the gas phase using density functional theory (DFT)$^{27-39}$ with Becke’s hybrid exchange, correlated three-parameter- and the Lee–Yang–Parr correlation functional (B3LYP)$^{40-42}$ utilizing standard basis sets: 6-311++G(2d,2p)$^{42,43}$ Afterwards the dipole moments (Fig. 1) and normal modes are calculated, according to which we assign the observed absorption bands to molecular vibrations (Table 1).

$^1$ $\alpha$-and $\beta$-fucose in furanose as well as pyranose forms for the $\nu_\alpha$- and $\nu_\beta$-stereo-isomers’ chair and boat conformations.

Fig. 1 Chemical structure of $\alpha$- and $\beta$-fucose in $\alpha$-fucofuranose form; the dielectric relaxations (dynamic glass transition (x relaxation), secondary $\beta$ and $\gamma$ relaxations) and IR active vibrational modes are indicated as well as the overall dipole moment. Oxygen, carbon and hydrogen atoms are di in red, grey and light grey, respectively.

3 Results and discussion

3.1 Analysis of spectra

Dielectric measurements above $T_\alpha$ reveal a broad intense relaxation process, the dynamic glass transition ($x$ relaxation), that shifts to lower frequencies upon decreasing temperature. At the calorimetric glass transition temperature the relaxation time is typically 100 s (Fig. 2). Additionally at these elevated temperatures a significant contribution due to dc conductivity is found as in many other carbohydrates. This is due to the proton conduction, as shown by Crofton and Pethrick$^{44}$ and later on by Kaminski et al.$^{45}$ Within the glassy state the time scale of structural relaxation exceeds the experimental frequency window. Instead, two secondary dielectric relaxation processes become accessible, labelled for our purpose as $\beta$ and $\gamma$ (Fig. 2a and b). This is a common scenario for monosaccharides such as $\nu$-glucose, fructose, galactose and $\nu$-sorbitose.$^{46}$ There are different views concerning the molecular origin of the slower relaxation mode ($\beta$). Authors discussed it as the genuine Johari–Goldstein relaxation of saccharides, relying on the pressure sensitivity of this mode.$^{46}$ But this process may also originate from the conversion between different conformations of the saccharide ring, whose existence has been proven by NMR, in particular there exist boat (B), half chair (H) and skew (S) conformations.$^{47}$ The faster ($\gamma$) relaxation processes result from motions of the hydroxymethylene (CH$_2$OH, Fig. 1) units as discussed earlier in the literature.$^{23}$ Comparing the BDS spectra of the two samples we find large dielectric strengths for $\gamma$-fucose compared to the $\nu$ form for all dielectric relaxations (Fig. 3b). This is attributed to the different overall dipole moment as discussed later on. But, apart from that no significant differences are observed in the BDS data.

To monitor intra-molecular interactions, FTIR measurements of $\nu$- and $\nu_\alpha$-fucose are performed above and below the calorimetric glass transition temperature (Fig. 2c and d). Because of mutarotation, different isomers are present in the sample with their respective concentrations depending on temperature.$^{26,48,49}$ Consequently, the IR spectrum of each tautomer of $\nu$- and $\nu_\alpha$-fucose, that can be formed during this chemical reaction, is calculated. It turns out that some of the bands are specific for some tautomers, whereas others originate from vibrations common to all isomeric species (Table 1). Upon lowering temperature the spectral positions, $\nu_{\text{max}}$, and oscillator strengths, $f_{\text{xx}}$, of the bands change characteristically. Similar to the dielectric measurements, we observe only slight deviations between $\nu_\alpha$- and $\nu$-fucose, particularly in the oscillator strengths of absorption bands at around 870 and 920 cm$^{-1}$ (Fig. 2d). This appears to be reasonable, as these bands have contributions from stretching vibrations of C–OH groups, whose dipolar character is influenced by the orientation of the chiral centre, if closely attached to it (compare Table 1 and Fig. 1).

3.2 Molecular dynamics

By fitting Havriliak Negami functions$^{50}$ to the loss spectra of both fucoses, relaxation times, $\tau$, as well as dielectric strengths, $\Delta\varepsilon$, of the $x$, $\beta$ and $\gamma$ relaxations are determined for all temperatures. The structural relaxation times (\tau_\gamma, cf. Fig. 3a)
follow the Vogel–Fulcher–Tammann (VFT) equation given by:

\[
\tau_2(T) = \tau_0 \exp\left(\frac{D_T T_0}{T - T_0}\right)
\]

(1)

where \(D_T\) is a measure of the fragility \((m = 134 \pm 2)\) of the analysed relaxation process, \(\tau_0\) is a pre-exponential factor and \(T_0\) is the Vogel temperature. By assuming \(\tau_2(T_g) = 100\) s the glass transition temperature of \(\nu\) and \(\alpha\)-fucose can be estimated to be
306 K and 304 K, respectively. These values are comparable to $T_g$'s of other six-carbon monosaccharides, e.g. D-glucose ($T_g = 308$ K), galactose ($T_g = 300$ K) sorbose ($T_g = 293$ K) or fructose ($T_g = 289$ K). The relaxation rates of secondary processes ($\tau_\beta$, $\tau_\gamma$) are described for low temperatures by the Arrhenius equation written as:

$$\tau(T) = \tau_0 \exp\left(\frac{E_a}{k_B T}\right)$$  \hspace{1cm} (2)$$

where $k_B$ is the Boltzmann constant. The activation energy, $E_a$, is found to be independent of chirality (i.e. equal in L and D form), in particular $E_a = 80$ kJ mol$^{-1}$ and $E_a = 38$ kJ mol$^{-1}$ for the $\beta$ and $\gamma$ processes, respectively. Similar activation barriers for the $\beta$ relaxation process in monosaccharides have been reported previously, in our case $E_a(\gamma)$ seems to be smaller compared to other saccharides such as glucose, galactose or
fructose (\(E_a = 42 \text{ kJ mol}^{-1}\)). This may be explained by a change in the H-bonding network resulting from the lower number of hydroxyl groups in fucose (4 OH groups) with respect to the other mentioned substances (5 OH groups). The qualitative behaviour of the dielectric strength (\(\Delta \epsilon\)) of the three accessible dielectric relaxations, as shown in Fig. 3b is the same in \(\nu\) and \(\nu\)-fucose. But there is a quantitative difference of roughly a factor of 2 that stems from the larger overall dipole moment of \(\nu\) compared to \(\nu\)-fucose. In particular, dipole moments of \(\mu = 4.7 \text{ D}, 5.6 \text{ D}, 1.6 \text{ D} \text{ and } 3.3 \text{ D} \) for \(\nu\)-fucopyranose, \(\nu\)-fucofuranose, \(\beta\)-fucopyranose and \(\beta\)-fucofuranose, respectively, are calculated, whereas the same tautomers of \(\nu\)-fucose exhibit \(\mu = 2.3 \text{ D}, 3.3 \text{ D}, 0.8 \text{ D} \text{ and } 1 \text{ D} \). In both, \(\nu\)- and \(\nu\)-fucose, the dielectric strength of the \(\nu\) and \(\gamma\) relaxation depends approximately linearly on inverse temperature. For \(T_g/T > 1.05\) this also seems to be the case for the \(\beta\) process that shows a strong, gradual increase as \(\Delta \epsilon\) as \(T\) approaches the glass transition temperature. The observed decrease in \(\Delta \epsilon\) of the secondary relaxations when lowering temperature is well known and ascribed to reduced density fluctuations that govern the amplitude of these motions.\(^{51}\) On the other hand, a drop in temperature increases the density of the sample, which enhances the dielectric strength of the \(\nu\) process as is observed for many glass forming liquids. Unfortunately, closer to \(T_g\) the \(\nu\) and \(\beta\) processes overlap strongly, resulting in an increased uncertainty of \(\Delta \epsilon\) and to a lesser extent in \(\tau_{\nu/\beta}\).

The spectral positions and oscillator strengths of the selected IR active vibrations are obtained by fitting combinations of pseudo Voigt functions to the FTIR data after subtracting a linear baseline.\(^{17,19,52}\) This gives excellent agreement for all analysed bands except for the case of the OH stretching band (\(\nu\)(OH)). This vibration is strongly asymmetrically broadened, most probably due to the presence of different types of hydrogen bonds (H-bonds) with varying binding energy, as described in the literature for different low and high molecular weight materials.\(^{18,53–55}\) The average binding energy, \(E_{\text{bind}}\), of such H-bonds was empirically correlated with the difference of the spectral position \(\nu_{\text{max}}\) of \(\nu\)(OH) in the H-bonded and free (non-H-bonded) state.\(^{56,57}\) Hence, considering the temperature dependence of the \(\nu\)(OH) vibration (cf. Fig. 2e and 3c) the binding energy varies from about \(-23\) to \(-19 \text{ kJ mol}^{-1}\) upon heating from 253 to 353 K. These energies compare well with the binding energy of the OH \(\cdot\cdot\cdot\) O bridge as determined from DFT calculations for a \(\text{CH}_2\text{OH} \cdot\cdot\cdot \text{fucose} \) interaction. We are not able to reliably deconvolve the peak into several contributions, since a clear indication of more than one peak could not be found neither in the second derivative nor in difference spectra. To overcome that and extract quantitative information anyway, we decided to approximate that band with an asymmetric pseudo Voigt function, as proposed by Stancik and Brauns.\(^{58}\)

The temperature dependencies of the results of all analysed vibrational absorptions are combined in Fig. 3c–f. Oscillator strength of almost each band analysed here increases with decreasing temperature as an effect of an increased contrast on the occupation number and in the case of \(\nu\)(OH) also because of an increased probability of H-bonding. Similarly, an increase of \(\nu_{\text{max}}\) is found with decreasing \(T\) for all bands (except \(\nu\)(OH)), which is attributed to thermal contraction resulting in a strengthening of the bond and, hence, its vibrational frequency. In the case of \(\nu\)(OH) the aforementioned effect is suppressed by a dramatic increase of probability and strength of hydrogen bonding that weakens the O–H bond by pulling away the hydrogen atom.\(^{18}\)

Analysing these dependencies in more detail, we find the OH stretching band at about 3400 \text{ cm}^{-1} to be sensitive to the dynamic glass transition in its spectral position and oscillator strength. This can be seen in the sharp change in the slope of \(\nu_{\text{max}}\) and \(f_{\nu}\) (when plotted versus \(T\) or \(T^{-1}\)) that originates from an accelerated formation of stronger H-bonds above \(T_g\).

The observed change in H-bonding may be the reason or the result of the macroscopic densification. Similar findings have been reported in the literature for other substances, all fitting into the picture of inter-molecular association driven by polar (electrostatic) interactions as an important factor of vitrification.\(^{12,52,59,60}\) Especially the correlation of \(T_g\) (\(~305\) K) and \(\nu_{\text{max}}\) (\(~3370 \text{ cm}^{-1}\)) of the \(\nu\)(OH) band as found by Imamura et al. for systems with five OH groups per ring is reproduced here.\(^{12}\) Several IR active moieties exhibit a kink in the temperature dependencies of their spectral positions around \(T_g\). These include major contributions of the following type (cf. Table 1): CC ring stretching (at 856 \text{ cm}^{-1}, named \(\nu\)(CC)), CH deformation (\(\delta\)(CH) at 876 \text{ cm}^{-1}), combinations of CCO ring stretching and CH deformation modes (\(\delta\nu\)(ring) at 900 \text{ cm}^{-1} and \(\delta\nu\)(ring) at 905 \text{ cm}^{-1}) as well as a CH deformation (\(\delta\)(CH) at 945 \text{ cm}^{-1}). All of these bands are linked to the conformation of the ring. There is no such direct relation for the combination band at 1170 \text{ cm}^{-1} (called \(\nu\)(CH\(_3\)) in the following), which exhibits major contributions from a C–CH\(_3\) stretching motion and minor parts from CH\(_2\) deformation. Consequently, we do not observe a kink here.

Plotting \(f_{\nu}\) vs. \(T_g/T\) displays such pronounced changes in the slope at \(T_g\) only for \(\nu\)(OH). All other analysed vibrations show a constant or a continuously varying slope for \(f_{\nu}(T_g/T)\) at this temperature. Surprisingly, a kink is observed for \(f_{\nu}\) of \(\nu\)(CC), \(\delta\nu\)(ring) and a weak one for \(\delta\nu\)(ring) well within the liquid state at \(T_g/T \sim 0.86\) (\(T = 354 \text{ K} = 1.16T_g\)). These 3 vibrations extend over the whole sugar ring and, hence, are sensitive to the intra-molecular structure. For example, \(\nu\)(CC) vanishes after transformation from chair to boat conformation of \(\alpha\)-fucose according to the DFT calculations. Furthermore, we find a weak change in the slope of \(\nu_{\text{max}}\) of \(\nu\)(OH) here (inset in Fig. 3f), similar dependencies at a ratio of \(T_g/T = 0.85 \pm 0.05\) have been reported for the carbonyl stretching band in citrates\(^{18}\) and salol\(^{16,17}\) indicating changes in the intra-molecular mobility. This temperature ratio resembles for fucose and the other two cases the point where the high temperature extrapolation of a secondary relaxation time matches \(\tau_s\), i.e. the point where structural and secondary processes merge. Changes in structural dynamics of various glass formers have been observed in that temperature range in several other studies.\(^{61}\) Novikov and Sokolov discussed it in terms of a particle that is trapped in a cage and can escape if the thermal fluctuations of the cage are large enough. They argue that this should happen at a “universal” \(\tau_s\) relaxation time of about \(10^{-6} \text{ s}\) to \(10^{-8} \text{ s}\),\(^{61}\) which agrees with the
\( \tau_z \) at \( T_d/T \sim 0.86 \) found here. In citrates the mentioned temperature is linked to the point where the \( \gamma \) and \( z \) relaxation decouple, which is at \( \tau_{z} \sim 10^{-7} \) s, whereas in salol we find the merging point of \( \beta \) and \( z \) at that characteristic temperature ratio, being at \( \tau_z \sim 10^{-2} \) s.\(^{17,18} \) So both examples contradict the explanation proposed by Novikov and Sokolov and indicate a more specific origin of the observed \( z \beta \) coupling. Here, for the case of fucose, we propose a molecular interpretation based on polar interactions of CH and OH groups. The importance of such CH\( \cdot \)OH interactions has been proven experimentally for a wide range of carbohydrate crystals by Steiner and Saenger\(^{62} \) and the corresponding interaction energies, \( E_{\text{CHO}} \), are subject of numerous computational studies.\(^{63-68} \)

In particular, for the \( \text{CH}_4\cdot\text{OH}_2 \) contact \( E_{\text{CHO}} \approx -2.9 \) kJ mol\(^{-1} \) is found by Ornstein and Zheng.\(^{68} \) Other authors got smaller values depending on the details of the calculations (e.g. \( E_{\text{CHO}} \approx -2.2 \) kJ mol\(^{-1} \) (ref. 66)), but certainly \( E_{\text{CHO}} \) is increased by electron-negative substituents. For \( \text{OHCH}_2\text{CHO} \) contacts, \( E_{\text{CHO}} \) of approximately \(-3.1 \) kJ mol\(^{-1} \) was reported by Novoa and Mota.\(^{67} \) These energies coincide with thermal energy at the extrapolated \( \beta z \) merging point being \( k_B T = k_B \cdot 1.16 T_0 = -2.9 \) kJ mol\(^{-1} \), where we observe a weak kink of \( \nu_{\text{max}} \) of \( \nu_{\text{OH}} \) (Fig. 3f). Therefore, we conclude that the dynamic barriers between structural substates are strengthened by the enhanced H-bonding network below 354 K = 1.16\( T_0 \), in contrast to the dynamic barriers of conformational fluctuations (\( \beta \)) that remain essentially unchanged. This is why we observe the splitting of the two relaxations, and the reduced changes in \( f_{\beta} \) of conformationally sensitive bands below 1.16\( T_0 \) (Fig. 3).

### 3.3 Aging dynamics

Besides the inter- and intra-molecular dynamics of \( \nu \)- and \( \sigma \)-fucose depending on temperature, the impact of physical aging is investigated. BDS spectra reveal a decrease in dielectric loss of the \( \beta \) and \( \gamma \) processes with time (Fig. 4a). This is a universal scenario for secondary relaxation processes in glass forming liquids, and is commonly attributed to a decrease of the average angle of reorientation or the number of reorienting dipoles.\(^{69-71} \)

Furthermore, changes in the dielectric spectra at low frequencies are observed being explained by the slowing down of the structural relaxation process. In contrast to that, no shift of the relaxation times of both secondary modes can be observed as aging proceeds (Fig. 4a). This means that time aging-time superposition is not fulfilled. This is in contrast to previous aging measurements on different H-bonded systems.\(^{72,73} \)

Here we apply an approach proposed by Casalini and Roland,\(^{74,75} \) to quantify the observed changes and estimate structural relaxation times in the glassy state, called “isostuctural relaxation times”. We adopt this term of the aforementioned study, although the shift of the \( \alpha \) relaxation indicates structural evolution upon aging. The time dependence of the dielectric loss, \( \varepsilon^\prime \), measured at fixed frequencies, \( f_c \), close to the maximum of the \( \beta \) and \( \gamma \) relaxation processes are fitted by the following equation derived by Leheny and Nagel (Fig. 4b).\(^{76} \)

\[
\varepsilon^\prime (f_c, t_{\text{ag}}) = \Delta\varepsilon^\prime (f_c) \exp \left( -\frac{t_{\text{ag}}}{\tau_{\text{ag}}} \right)^{\beta_{\text{ag}}} + \varepsilon_{\text{eq}}^\prime (f_c) \tag{3}
\]

where \( \varepsilon_{\text{eq}}^\prime (f_c) = \varepsilon (f_c, t_{\text{ag}} \to \infty) \) is the equilibrium value of \( \varepsilon^\prime \) and \( \Delta\varepsilon^\prime (f_c) = \varepsilon^\prime (f_c, t_{\text{ag}} = 0) - \varepsilon_{\text{eq}}^\prime (f_c) \) is the change in \( \varepsilon^\prime \) during aging. \( t_{\text{ag}} \), the aging time constant, is identified with the isostuctural relaxation time. \( \beta_{\text{ag}} \) is the stretching exponent that does not vary significantly with temperature and is assumed to be equal to

![Figure 4](image-url)

KWW, as obtained from fitting the Kohlrausch–Williams–Watt (KWW) function to the structural loss peak measured just above $T_g$. In the case of L-fucose, $\beta_{\text{KWW}} = 0.5$ is used as a fixed parameter during fitting.

The isostuctural relaxation times, $\tau_{\text{ag}}$, obtained from the slow and fast secondary relaxation processes agree and are shown in Fig. 3a. That there is no frequency dependence of $\tau_{\text{ag}}$ (cf. Fig. 4b) has been reported before for similar sugars well below $T_g$. So there is only a single mechanism governing the rate exchange during aging. Furthermore, we have to mention that the time scale of mutarotation is at least 2 orders of magnitude larger than $\tau_{\text{ag}}$ and, hence, there should be no

\]
influence of it. Unfortunately, the results of $\tau_{ag}$ are somehow scattered, but change by less than an order of magnitude within the analysed temperature interval of 15 K.\(^{26,73} \) The application of different analysis methods, e.g. as proposed by Lunkenheimer et al.,\(^{72,73} \) does not lead to systematically different results.

Studying physical aging by FTIR spectroscopy yields small, but significant, changes in the obtained spectra. This is exemplified in Fig. 5, where differences between the spectra at the beginning and end ($t = 4$ h) of the experiment are barely visible with the naked eye, but become obvious when magnified difference spectra are analysed. Especially for the $\nu$(OH) band a clear red shift of $\nu_{max}$ and an asymmetric increase in $f_{gj}$ can be observed as well as smaller changes within the fingerprint region. By application of the fitting procedure, as described above for the temperature dependent measurements, these subtle changes are quantified. Bands exhibiting a reasonably large variation in $\nu_{max}$ or $f_{gj}$ (Fig. 5) are fitted with a stretched exponential function equivalent to eqn (3):

$$A(t_{IR}) = \Delta A \exp \left[- \left(\frac{t_{IR}}{t_{IR}^*}\right)^{\beta_{IR}}\right] + A_{eq}$$

$A(t_{IR})$ is the spectral position or oscillator strength at aging time $t_{IR}$ or in thermal equilibrium (i.e. $A(t_{IR} \to \infty) = A_{eq}$). The stretching exponent, $\beta_{IR}$, is used as a shared parameter for all the dependencies of $\nu_{max}$ and $f_{gj}$ on time and converged to a value of 0.46, which is remarkably close to the dielectric case (cf. Fig. 6). The extracted time constants, $t_{IR}^*$, follow smooth and neither Arrhenius nor VFT like curves that, surprisingly, interlink the dielectrically determined structural, $\tau_s$, and isostuctural times, $\tau_{ag}$ well (Fig. 3a). Such dependencies have been reported previously for different systems.\(^{80-83} \) Moreover, $t_{IR}^*$ of $\nu$(OH) coincides with the time constant from BDS at $T = 273$ K within experimental accuracy. This coincidence over such a wide temperature range indicates that $\tau_{ag}$ can be identified with $\tau_s$ below $T_g$ at least in strongly H-bonding systems; and, furthermore, it underscores the role of the H-bonding network for the structure and the inter-molecular dynamics of l-fucose as reported for different systems by Gainaru et al.\(^{84} \) and Preuß et al.\(^{85} \) The IR aging times of $\delta_2$(CH) appear to follow a steeper dependence than $\nu_{max}$ and $f_g$ of $\nu$(OH) differing by a factor of up to 3. This significantly exceeds the experimental uncertainties. Unfortunately, only three rates can be extracted for $\delta_2$(CH), which forbids further conclusions. But considering the sensitivity of $\delta_2$(CH) to the intra-molecular structure, the observed differences between $t_{IR}^*(\nu$(OH)) and $t_{IR}^*(\delta_2$(CH))) are rationalized at least qualitatively. The significant difference, of up to a factor of 2, observed when comparing rates determined from oscillator strength and the spectral position of the $\nu$(OH) band can be explained by the following: $f_g$ is proportional to the transition probability and the change in dipole moment when exciting $\nu$(OH), whereas $\nu_{max}$ depends on the energy of the hydrogen bond amongst others. These 3 quantities vary differently with

\[\text{structural changes, e.g. with the changing distance of two hydroxyl groups.}^{17,56,57}\]

4 Conclusion

The inter- and intra-molecular dynamics of D- and l-fucose are studied in a wide range of temperatures below and above the calorimetric glass transition temperature $T_g$ by combining dielectric and IR-spectroscopic measurements. For the different intra-molecular vibrations characteristic temperature dependencies of their spectral positions and oscillator strengths are found: while, for instance, the OH stretching vibration $\nu$(OH) shows a pronounced kink at $T_g$, the $\nu$(CCH$_3$) vibration does not perform any discontinuity at this temperature. Coupling of intra- and inter-molecular dynamics takes place at $T \sim 1.16T_g$ ($T_g/T \sim 0.86$), where the $\varepsilon$ relaxation merges with the extrapolated $\beta$ relaxation. Here the OH stretching vibration shows a kink in the temperature dependence of the spectral position, and conformationally sensitive vibrations, like $\nu$(CC), exhibit a change in the slope of the oscillator strength. This is explained by attractive CH···O interactions that strengthen the H-bonding network and slow down the $\varepsilon$ relaxation with respect to conformational fluctuations ($\beta$). Physical aging below $T_g$, attributed solely to the equilibration of the H-bonding network, reveals a bending off of the aging dynamics from the equilibrium VFT dependence, indicating no divergence of the structural relaxation time. Furthermore, both stereoisomers show quite similar temperature dependencies in the BDS and FTIR experiments.
