ABSTRACT: Sunlight exposure is a control of long-term plastic fate in the environment that converts plastic into oxygenated products spanning the polymer, dissolved, and gas phases. However, our understanding of how plastic formulation influences the amount and composition of these photoproducts remains incomplete. Here, we characterized the initial formulations and resulting dissolved photoproducts of four single-use consumer polyethylene (PE) bags from major retailers and one pure PE film. Consumer PE bags contained 15−36% inorganic additives, primarily calcium carbonate (13−34%) and titanium dioxide (TiO_2; 1−2%). Sunlight exposure consistently increased production of dissolved organic carbon (DOC) relative to leaching in the dark (3- to 80-fold). All consumer PE bags produced more DOC during sunlight exposure than the pure PE (1.2- to 2.0-fold). The DOC leached after sunlight exposure increasingly reflected the ^{13}C and ^{14}C isotopic composition of the plastic. Ultrahigh resolution Fourier transform ion cyclotron resonance mass spectrometry revealed that sunlight exposure substantially increased the number of DOC formulas detected (1.1- to 50-fold). TiO_2-containing bags photochemically degraded into the most compositionally similar DOC, with 68−94% of photoproduced formulas in common with at least one other TiO_2-containing bag. Conversely, only 28% of photoproduced formulas from the pure PE were detected in photoproduced DOC from the consumer PE. Overall, these findings suggest that plastic formulation, especially TiO_2, plays a determining role in the amount and composition of DOC generated by sunlight. Consequently, studies on pure, unweathered polymers may not accurately represent the fates and impacts of the plastics entering the ocean.

1. INTRODUCTION

Despite sustained attention from stakeholders, the ultimate fate of marine plastic remains an open question. Historically, stakeholders have assumed that plastics are inert in the environment, with only physical changes occurring.[1−5] That is, sunlight was once thought to only fragment plastics, producing increasingly small pieces, known as micro- and nanoplastics, that chemically resemble the original material.[2,3,6] We now know that sunlight also chemically transforms plastics, releasing a suite of polymer-, dissolved-, and gas-phase products.[7−15] Despite evidence that photo-oxidation to dissolved organic carbon (DOC) is an important fate of plastics, little is known about the chemical composition of these transformation products.

Orbitrap mass spectrometry (MS) revealed the production of hundreds of water-soluble compounds during ultraviolet (UV) irradiation of several pure polymers.[10,14,15] However, the achieved mass resolving power of Orbitrap MS is 10−15-fold lower than that of Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) and its high ion number populations result in peak coalescence, which suggests that we may be underestimating the complexity of plastic photoproducts.[16−20] Moreover, these initial studies used pure polymers[10] or polymers containing atypical additives,[14,15] which may not be representative of the plastics in the environment.

The plastics we use and leak into the environment are widely known to be complex mixtures of polymers and additives,[21−23] which may influence photochemical behavior.[7,24] Organic and inorganic additives are common and diverse. Additives are used as fillers (to improve appearance, alter physical properties, and/or reduce cost), pigments, plasticizers, and more.[22] Little is known about the impacts of plastic formulation on its fate and effects, as studies on marine plastics have generally used pure polymers. However, several recent studies have shown that additive-containing plastics behave differently than pure polymers: photochemical mineralization to CO_2,[7] photo-oxidation pathways,[7,24] lability of photoproducts to microbes,[25] and leachate toxicity[26] differed between pure and additive-containing polymers. These early studies suggest that the formulations of plastics in the environment may influence their breakdown by sunlight, but this link remains unconstrained.

In the present work, we aimed to connect the formulations of single-use consumer polyethylene (PE) bags from major retailers to the amount and composition of DOC produced during sunlight exposure. To achieve this, we first characterized the compositions of four consumer PE bags and one pure PE film. We then irradiated all PE types, measured DOC production, and characterized the composition of the DOC using negative ion electrospray coupled to ultrahigh resolution 21 tesla FT-ICR-MS. We find that plastic formulation substantially influences the amount and chemical composition of DOC generated upon exposure of plastic to sunlight, suggesting that formulation is an emerging control of its fate in sunlit waters.

2. METHODS

2.1. Plastic Sources. We chose to conduct these experiments on consumer PE bags because these bags are commonly found in beach surveys[27] and relevant to regulatory and consumer decision-making.[4] PE is also the most widely produced polymer,[21] the most commonly detected in the ocean,[28] and buoyant in seawater,[1] making it susceptible to sunlight exposure. Four consumer PE bags were characterized (Figure S1): conventional disposable shopping bags from Target, CVS, and Walmart and a postconsumer bag from a CVS located in a municipality with a plastic bag ban. An additive-free low-density PE film (Goodfellow) served as a control. Film thickness was measured in duplicate with a NIST-calibrated Mitutoyo micrometer with a precision of 1 μm. The Target bags were 26 $\pm$ 2 μm [$\pm$1 (standard deviation) SD] thick and white with red writing. The Walmart bags were 19 $\pm$ 2 μm thick and gray with blue writing. The postconsumer CVS bags were 79 $\pm$ 6 μm thick and off-white with red writing. The conventional CVS bags were 17 $\pm$ 2 μm thick and white with red writing. The pure PE was 59 $\pm$ 2 μm thick and clear. The text-free areas of the bags were used in experiments. All plastic was cleaned with MilliQ water prior to analysis.

2.2. Characterization of Plastic Optical Properties. UV and visible light absorbance were determined for each bag from transmittance and reflectance measurements on a PerkinElmer Lambda 650s spectrophotometer. Each bag was cut into ~2.5 cm $\times$ ~2.5 cm squares. Transmittance, T, was measured using the transmission port and reflectance, R, was measured using the reflectance port. Absorbance, A, was calculated from the T and R measurements. Absorbance was then converted to Naperian absorption coefficients (a; m^{-1}) by multiplying A by ln(10) and dividing by the film thickness (m).[29]

2.3. Characterization of Additives. Loss on ignition (LOI) measurements were used to determine the organic contents of the bags, with the assumption that leftover ash represents all inorganic additives. The procedure was based on ASTM D 2974-87, the method for determining the ash content of organic matter.[29,30] Briefly, ~1 g of each bag ($n = 3$) was placed in a precombusted, preweighed ceramic crucible and combusted at 450 °C for 8 h. The ash-containing crucible was then reweighed. Samples were also analyzed for the elemental carbon and hydrogen contents (Midwest Microlab), providing an indirect assessment of the presence of organic additives (Appendix 1).

The consumer PE bags and pure PE were sent to the Cambridge Polymer Group for quantification of Ca and Ti via inductively coupled plasma mass spectrometry (ICP−MS) using methods similar to those validated and described

previously.[31] All samples were run in duplicate, apart from the Target bag, which was run in triplicate. Samples were digested using microwave heating in a solution containing fluoroboric acid, nitric acid, and phosphoric acid in water. After dilution, samples were analyzed on a PerkinElmer Nexion 350X ICP−MS. The limits of quantification (LOQs) were 5.0 μg/g for both Ca and Ti. X-ray diffraction (XRD) was used to identify and quantify the mineral additives within the plastic bags following methods described previously (Appendix 2).[32]

2.4. Quantification of DOC Leached in the Dark and Produced by Sunlight. Leaching of DOC in the dark and during sunlight exposure was measured during two separate experiments. First, DOC was produced for analysis via FT-ICR-MS. These experiments were conducted in 300 mL precombusted beakers (450 °C for 4 h) containing 250 mL of MilliQ water (pH ~ 8) covered with quartz lids to avoid contamination from the air. MilliQ water was used instead of seawater to minimize salt suppression during ionization[33] and avoid masking of the plastic-derived DOC signal by natural seawater DOC (MilliQ DOC concentration was <2 μM for these experiments). The results of several experiments demonstrate that the photochemical behavior of plastics in MilliQ water is representative of behavior in natural waters (Appendix 3). To ensure sufficient DOC production, plastic was cut into ~3 cm $\times$ ~1 cm pieces and ~0.5−4.2 g was used for the dark controls and ~0.5 g was used for the light-exposed samples. The light-exposed Target, conventional CVS, and postconsumer CVS bags were run in duplicate, while a single sample was run for all others. Dark controls were covered in foil, then placed in a dark drawer for 6 days at room temperature. Light-exposed beakers were placed inside an Atlas XLS+ solar simulator equipped with a long-arc Xe lamp and Daylight filter (Ametek Inc.) in a custom anodized water bath connected to a chiller, which maintained the beakers at 25 $\pm$ 5 °C during the experiment. A NIST-calibrated spectral radiometer (StellarNet, Inc.) was used to quantify irradiance. Relative to natural sunlight at 0 and 50°N, simulated sunlight was 4- and 12-fold greater, respectively (Figure S2 and Table S2). After 5 days of irradiation or 6 days in the dark, the mass of the water was measured and samples were filtered through a GF/F filter. MilliQ was added to account for evaporation in the light-exposed samples. Samples were then acidified to pH ~ 2 with trace metal grade 6 N hydrochloric acid (HCl) and analyzed for DOC concentration on a Shimadzu 5000A TOC analyzer.

The remaining DOC was extracted from samples using Agilent Bond Elut PPL cartridges, following Dittmar et al.[34] After cleaning the cartridge with 2 mL methanol, samples were loaded onto the cartridge at a flow rate of ~30 mL/min. After loading the samples onto the cartridges, 2 mL of 0.01 M HCl was passed through the cartridge. Immediately after, samples were dried under vacuum for 5 min. Finally, samples were eluted with 1 mL methanol directly into combusted 2 mL vials. While DOC recoveries were not determined, previous studies have reported incomplete recoveries on the order of 60% for seawater DOC[34] and terrestrial DOC.[35] Incomplete recoveries via PPL extraction indicate that DOC complexity was underestimated. We do not anticipate substantial differences in recoveries between samples because all plastic-derived DOC shared similar, wide-ranging elemental compositions. Extracts were shipped on ice overnight for FT-ICR-MS analysis.

Separately, a time series experiment was conducted using the postconsumer CVS bag. For both the light-exposed and dark
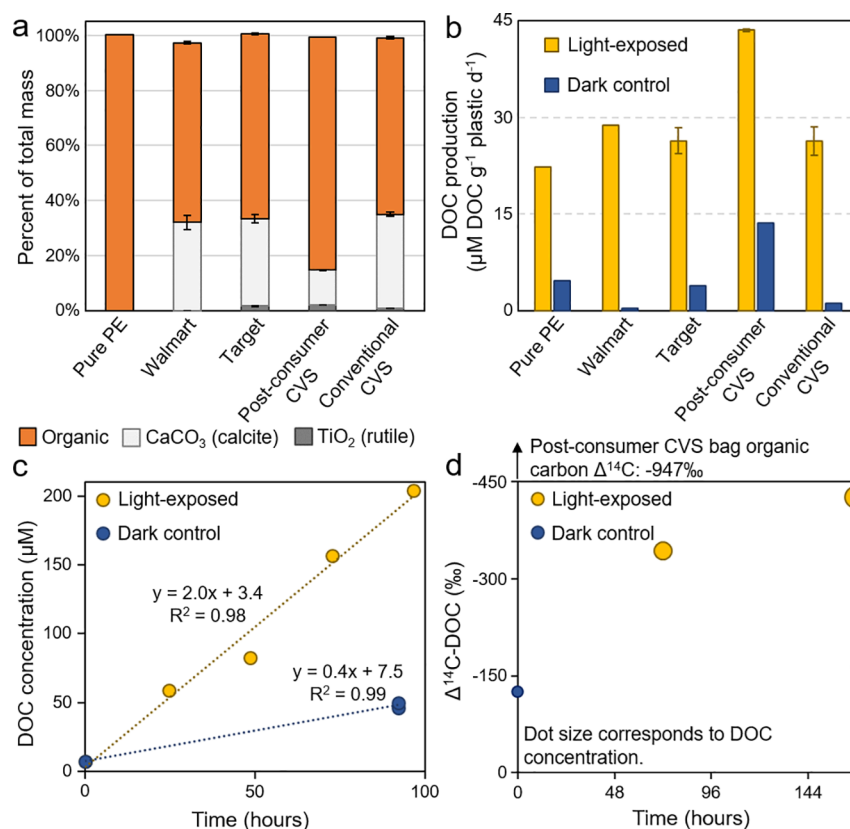

Figure 1. (a) Composition breakdowns for each sample, with organic percent from LOI and $CaCO_3$ and TiO_2 percent from ICP−MS. Mineral form was determined via XRD. Error bars represent ±1 SD ($n = 2-3$). (b) DOC produced by pure PE and consumer PE bags during exposure to simulated sunlight and in the dark normalized by the mass of plastic and exposure time. Error bars represent ±1 SD ($n = 1-2$) (c) DOC produced by the postconsumer CVS bag during 1, 2, 3, and 4 days of exposure to simulated sunlight, alongside dark controls at 0 and 4 days. (d) $\Delta^{14}C$ of DOC produced by the postconsumer CVS bag during exposure to simulated sunlight and in the dark. Dot size corresponds to the DOC concentration (Table S5).

control samples, ∼5 g of plastic cut into ∼1 × ∼8 cm strips were placed floating on top of ∼2.3 L MilliQ water in a combusted Pyrex dish (34 × 23 cm). The dish was placed inside the solar simulator in a water bath, which maintained the plastic at 30 ± 5 °C during the experiment, and covered with UV-B and UV-A transmitting acrylic (Arkema Inc.), which served as a thermal barrier by absorbing infrared light. In this configuration, simulated sunlight was 3- and 12-fold greater than natural sunlight at 0 and 50°N, respectively (Figure S3 and Table S3). An initial ∼35 mL sample was taken immediately after placing the plastic in the water. After 1, 2, 3, and 6 days of irradiation, ∼35 mL water samples were taken from the dish and an equivalent amount of MilliQ water was replaced in the dish. Simultaneously, a dark control covered in foil was kept in the dark and ∼35 mL samples were taken in duplicate after 6 days. All samples were then analyzed for DOC concentration.

2.5. Isotopic Characterization of DOC Leached in the Dark and Produced by Sunlight. Natural abundance radiocarbon measurements were leveraged to track the conversion of the postconsumer CVS bag to DOC. The same configuration from the time series experiment was used, with some modifications. The experiments were conducted in Vineyard Sound seawater filtered with GF/F and Sterivex filters to ensure that all samples had a sufficiently high background DOC concentration to obtain a robust determination of the radiocarbon content.[36] Seawater also contains DOC that is more modern than the fossil OC in the PE,

increasing the potential to see large shifts in DOC $\Delta^{14}C$ as the PE-derived DOC is added to the pool during irradiation. Separate exposures were run for 3 and 7 days and separate dark controls were included for 0 (i.e., water was sampled immediately after placing the plastic in it) and 7 days. All samples were filtered into a combusted 500 mL bottle using a GF/F filter and submitted to the National Ocean Sciences Accelerator Mass Spectrometry facility for $\delta^{13}C$ and $\Delta^{14}C$ measurements. Initial carbon isotope measurements of the bulk, organic, and inorganic fractions of the postconsumer CVS bag were taken in duplicate using a novel two-step method described in Appendix 4.

2.6. Characterization of DOC Leached in the Dark and Produced by Sunlight Using FT-ICR-MS. DOC composition was characterized using the 21 tesla (T) FT-ICR-MS at Florida State University's National High Magnetic Field Laboratory using methods described in Appendix 5.[19,20] In short, water-soluble extracts were infused directly into the mass spectrometer at 0.5 μL/min for negative-ion (−) electrospray ionization (ESI) analysis. The light-exposed Target, conventional CVS, and postconsumer CVS bags were run in duplicate, while a single sample was run for the light-exposed Walmart bag and pure PE and all dark controls. Predator analysis[37] and PetroOrg[38] software were used for internal "walking" calibration[39] of absorption mode spectra[40] and subsequent elemental composition assignments.

3. RESULTS

3.1. Characterization of Plastic Optical Properties.
The UV and visible light absorption spectrum of the pure PE was distinct from that of the consumer-grade PE (Figure S4). The pure PE showed minimal light absorption throughout the UV and visible regions, as expected for pure PE.[41] In contrast, all bags had absorption spectra distinct from the pure PE, suggesting the presence of additives. The Target, conventional CVS, and postconsumer CVS bags showed similar, strong absorption across the UV, followed by a sharp decline in absorption at ∼400 nm. This spectral shape is characteristic of TiO_2.[42] The Walmart bag instead showed strong absorption across the UV and visible regions, characteristic of the absorption properties of carbon black.[43]

3.2. Characterization of Additives.
LOI measurements demonstrated that the pure PE was indeed free of inorganic additives, while the consumer PE bags were not. $100 \pm 0.1\%$ (± 1 SD, $n = 3$) of the pure PE was lost on ignition (Figure 1a and Table S4), indicating that only organic material was present. In contrast, LOI was consistently below 100% for all consumer PE bags. The postconsumer CVS bag had the highest LOI value among the bags, with $85 \pm <0.1\%$, followed by the Target bag with $67 \pm 0.3\%$, the Walmart bag with $65 \pm 0.5\%$, and the conventional CVS bag with $64 \pm 0.1\%$. This result indicated that approximately 15, 33, 35, and 36% of the masses of the postconsumer CVS, Target, Walmart, and conventional CVS bags, respectively, were inorganic additives. Elemental analysis suggests that the organic fractions of all materials were predominantly PE (Appendix 1 and Table S1).

The absence and presence of inorganic additives in the pure PE and consumer PE bags, respectively, were confirmed by ICP−MS. In the pure PE, Ca and Ti were below or near their respective LOQs (Table S4). In contrast, Ca and Ti in all consumer PE bags were orders of magnitude above the LOQs. The conventional CVS bag had the highest Ca concentration (136 ± 3.1 mg/g; ± 1 SD, $n = 2$), followed by the Walmart and Target bags (130 ± 10 and 130 ± 6.3 mg/g, respectively), and the postconsumer CVS bag (51 ± 0.9 mg/g). Relative to Ca, much lower concentrations of Ti were observed in the consumer PE bags. The postconsumer CVS bag had the highest concentration of Ti ($13 \pm <0.005$ mg/g), followed by the Target bag (11 ± 0.6 mg/g), the conventional CVS bag (6.5 ± 0.07 mg/g), and the Walmart bag (0.7 ± 0.01 mg/g). By assuming that Ca and Ti are primarily added to plastics as $CaCO_3$ and TiO_2, we calculated that the Walmart bag contained $32 \pm 2.6\%$ $CaCO_3$ and $0.1 \pm 0.001\%$ TiO_2, the Target bag contained $32 \pm 1.6\%$ $CaCO_3$ and $1.8 \pm 0.1\%$ TiO_2, the postconsumer CVS bag contained $13 \pm 0.2\%$ $CaCO_3$ and $2.2 \pm <0.001\%$ TiO_2, and the conventional CVS bag contained $34 \pm 0.8\%$ $CaCO_3$ and $1.1 \pm 0.01\%$ TiO_2.

XRD confirmed our assumption that $CaCO_3$ and TiO_2 were the major inorganic additives in the PE bags (Figures 1a, S5 and Table S6). Neither $CaCO_3$ nor TiO_2 was detected in the pure PE. In contrast, the Target, conventional CVS, and postconsumer CVS bags contained calcite and rutile, which were the only detectable crystalline components in each bag. The proportions of $CaCO_3$ and TiO_2 relative to the total mass of inorganic additives were 86.7 ± 1.9 and $13.2 \pm 1.1\%$, respectively, in the postconsumer CVS bag, 95.0 ± 1.9 and $5.1 \pm 1.2\%$, respectively, in the Target bag, and 97.6 ± 1.0 and $3.4 \pm 0.9\%$, respectively, in the conventional CVS bag (± 1 SD, $n =$

3). The only detectable crystalline structure in the Walmart bag was calcite.

Combining the LOI, ICP−MS, and XRD results achieved 100% mass balances of the compositions of each PE sample (Figure 1a). Moreover, excellent agreement was observed between the LOI, ICP−MS, and XRD data. Plotting the sum of $CaCO_3$ and TiO_2 calculated from the ICP−MS data against the ash content from LOI yields a nearly 1:1 line ($R^2 = 0.97$) (Figure S6). Similarly, plotting the percent of $CaCO_3$ (relative to TiO_2) measured via ICP−MS against the percent measured via XRD also yields a nearly 1:1 line ($R^2 = 0.99$) (Figure S7).

3.3. Quantification of DOC Leached in the Dark and Produced by Sunlight.
For the pure PE and the consumer PE bags, a small amount of DOC leached in the dark, but a much greater amount leached in the presence of sunlight (Figure 1b). In the dark controls, the smallest amount of DOC leached out of the Walmart bag (0.35 μM DOC g^{-1} plastic d^{-1}), followed by the conventional CVS bag (1.2 μM DOC g^{-1} plastic d^{-1}), the Target bag (3.8 μM DOC g^{-1} plastic d^{-1}), the pure PE (4.6 μM DOC g^{-1} plastic d^{-1}), and the postconsumer CVS bag (14 μM DOC g^{-1} plastic d^{-1}). Following light exposure, DOC concentration increased for all samples. The pure PE had the lowest difference between light-exposed and dark control DOC production, at 18 μM DOC g^{-1} plastic d^{-1}. Among the consumer PE bags, the postconsumer CVS bag had the greatest difference between light-exposed and dark control DOC production, followed by the Walmart, conventional CVS, and Target bags, at 30 ± 0.2 μM DOC g^{-1} plastic d^{-1} (± 1 SD, $n = 2$), 28 μM DOC g^{-1} plastic d^{-1} ($n = 1$), 25 ± 2.2 μM DOC g^{-1} plastic d^{-1} ($n = 1$), and 23 ± 2.0 μM DOC g^{-1} plastic d^{-1} ($n = 2$), respectively. This represents 3.2-, 4.8-, 6.9-, 23-, and 83-fold increases from dark to light DOC production for the postconsumer CVS bag, pure PE, Target bag, conventional CVS bag, and Walmart bag, respectively.

Increasing durations of sunlight exposure led to an increasing amount of DOC leaching from the postconsumer CVS bag (Figure 1c). After 97 h of irradiation with simulated sunlight, 154 μM DOC were produced. The increase over four time points was linear ($R^2 = 0.98$). In contrast, the dark control DOC concentration increased to only 48 ± 2.7 μM ($n = 2$) after 92 h.

3.4. Isotopic Characterization of DOC Leached in the Dark and Produced by Sunlight.
Initial measurements of the postconsumer CVS bag's isotopic signature confirmed that the organic carbon was primarily fossil ($\delta^{13}C = -29.4\permil$; $\Delta^{14}C = -947\permil$; Table S5), consistent with petroleum feedstocks. The small amount of modern carbon was likely due to modern additives or impurities from the manufacturing process. The inorganic carbon also showed a fossil radiocarbon signature, but $\delta^{13}C$ was substantially more enriched ($\delta^{13}C = -6.3\permil$ and $\Delta^{14}C = -970\permil$), consistent with the limestone typically used for calcium carbonate fillers.

Natural abundance radiocarbon measurements confirmed that the postconsumer CVS bag was converted to DOC (Figure 1d and Table S5). The 0 day dark control was consistent with coastal seawater [(DOC) = 101 μM; $\delta^{13}C$ lost during measurement; $\Delta^{14}C = -126\permil$]. The 7 day dark control showed a small decrease in $\Delta^{14}C$, consistent with leaching of fossil DOC from the plastic ([DOC] = 83 μM; $\delta^{13}C = -23.8$; $\Delta^{14}C = -163\permil$). The slight decrease in DOC in the dark is likely due to experimental differences in C recovery.[36] Light-exposed samples showed appreciable increases in DOC concentration and decreases in DOC $\delta^{13}C$ and

Δ^{14}C corresponding to DOC production from the plastic. After 3 days of irradiation, the DOC concentration increased by 78 μM, relative to the average of the dark controls, and δ^{13}C and Δ^{14}C decreased to −26.6 and −343‰, respectively. After 7 days of irradiation, the DOC concentration increased by 100 μM, relative to the average of the dark controls, and δ^{13}C and Δ^{14}C decreased to −27.1 and −424‰, respectively. Isotopic mass balance calculations revealed that photo-produced DOC had a more modern signature than expected, based on the measured organic carbon isotope signature of the initial plastic (Appendix 4). After 3 and 7 days of light exposure, the calculated Δ^{14}C of the DOC added from the plastic was −585 and −689‰, respectively, whereas the measured Δ^{14}C of the organic carbon fraction of the plastic was −947‰. This result suggests that the modern carbon additives were preferentially oxidized to DOC, but, with time, the proportion of fossil, polymer-derived DOC increases. Alternative and less likely interpretations of the results include the preferential mineralization of aged DOC in the marine DOC pool and enhanced leaching of oxygenated, water-soluble organic additives after sunlight exposure (Appendices 1, 4 and Table S1).

3.5. Characterization of DOC Leached in the Dark and Produced by Sunlight Using FT-ICR-MS. The number of assigned formulas in DOC that leached in the dark ranged widely depending on the type of PE (Figures 2, S8 and Table

Figure 2. Negative ion ESI 21 T FT-ICR mass spectra of peaks unique to dark control (black) and photoproduced DOC (orange) for the conventional CVS bag. This bag is generally representative of the trends observed for all samples (Figure S8).

S7). The pure PE had 1464 formulas unique to the dark control. A range spanning 2 orders of magnitude was observed for the consumer PE bags: the conventional CVS bag contained the fewest formulas unique to the dark control (263), followed by the Target (476), Walmart (1387), and postconsumer CVS (11,027) bags.

By most metrics, average DOC chemical composition leached in the dark from the pure PE and the bags was similar

(Figure 3 and Table S7). The average molecular weight for the pure PE was similar to the consumer PE bags, at 537, compared to 445, 486, 626, and 642 for the Target, conventional CVS, postconsumer CVS, and Walmart bags, respectively. The average carbon number for the pure PE was 30, while the average was 23 for the Target bag, 28 for the conventional CVS bag, 33 for the postconsumer CVS bag, and 38 for the Walmart bag. The average number of oxygen atoms was eight in the pure PE, compared to six in the conventional CVS and Walmart bags, seven in the Target bag, and 11 in the postconsumer CVS bag. Average H/C ratios overlapped, with 1.5 in the pure PE, Target, and conventional CVS bags, 1.4 in the postconsumer CVS bag, and 1.3 in the Walmart bag. O/C ratios were also similar, with the pure PE and Target bag at 0.3, the postconsumer CVS bag at 0.4, and the Walmart and conventional CVS bags at 0.2. All replicates showed consistent trends.

Sunlight exposure substantially increased the number of DOC formulas leached from all PE samples (Figures 2, S8 and Table S7). The pure PE had among the fewest formulas in the light-exposed sample (9030). Of the bags, the Walmart bag had the most formulas (15,353), followed by the conventional CVS (13,052), postconsumer CVS (12,312), and Target bags (5359). The pure PE increased by 6-fold from dark to light. Among the consumer PE bags, the largest increase was observed for the conventional CVS bag (50-fold), followed by the Target and Walmart bags (11-fold), and the postconsumer CVS bag (1.1-fold).

The composition of the DOC leached in the dark and produced by sunlight showed many similarities, but average carbon numbers and molecular weights were noteworthy exceptions (Figures 3, S8 and Table S7). These differences were generally larger for consumer PE bags, especially those containing TiO_2. Average carbon numbers were consistently greater in the photoproduced DOC than in the DOC leached in the dark, with the lowest observed for the pure PE, at 30, followed by 32 for the Target bag, 38 for the conventional CVS bag, 39 for the postconsumer CVS bag, and 40 for the Walmart bag. A similar trend was observed for average molecular weight: the pure PE was among the lowest, at 608, compared to 583, 663, 688, and 698 for the Target, conventional CVS, Walmart, and postconsumer CVS bags, respectively. Average numbers of oxygen atoms increased for most samples, while H/C ratios and O/C ratios remained similar for dark control and light-exposed samples.

Sunlight exposure converted the pure PE into DOC that was compositionally distinct from the DOC produced from the consumer PE bags (Figures 3, S8, S9 and Table S8). The pure PE contained the highest percent of unique formulas (72%) relative to the photoproduced DOC from the other samples (6−41%). The formulas unique to the bags were more tightly clustered in van Krevelen space, with H/C ratios ranging from ∼1−2 and O/C ratios from ∼0.2−0.5. In contrast, the pure PE showed a greater spread, with H/C ratios ranging from ∼0.7− 1.9 and O/C ratios from ∼0.1−0.9. Photoproduced DOC unique to the pure PE was more oxidized and lower molecular weight compared to photoproduced DOC unique to the consumer bags.

Consumer PE bag composition further influenced photo-produced DOC composition. The greatest similarities were observed between the three TiO_2-containing bags, for which 68−94% of photoproduced formulas in each TiO_2-containing bag were shared with those generated by at least one other
Figure 3. van Krevelen diagrams showing (a) formulas unique to the conventional CVS bag dark control relative to the light-exposed sample, (b) formulas unique to the light-exposed conventional CVS bag relative to the dark control, (c) a comparison between formulas found only in photoproduced DOC from consumer PE bags (Walmart, Target, and conventional and postconsumer CVS bags), shown in red, and formulas found only in photoproduced DOC from the pure PE, shown in blue, and (d) a comparison between the formulas found only in photoproduced DOC from the TiO_2-containing bags (Target and conventional and postconsumer CVS bags) (pink) and formulas found only in photoproduced DOC from the Walmart bag (black).

TiO_2-containing bag (Figure 3 and Table S8). The Walmart bag shared 43% of formulas with at least one other consumer PE bag. In contrast, only 28% of the photoproduced formulas from the pure PE were detected in any of the consumer bags. Put another way, the TiO_2-containing bags had nearly 4000 formulas in common between all three, substantially more than the Walmart bag (~2600). The pure PE shared only ~700 formulas with all bags. Formulas unique to the TiO_2-containing bags clustered more tightly across van Krevelen space, with H/C ratios ranging from ~1.2−1.9 and O/C ratios ranging from ~0.2−0.5. In contrast, the formulas unique to the Walmart bag spread widely across van Krevelen space, with H/C ratios ranging from ~0.4−2.4 and O/C ratios ranging from ~0−0.8. Consistent with the compositional differences observed in the van Krevelen diagrams, the percent (by mass) of inorganic additives was significantly inversely correlated with the average number of oxygen atoms in the formulas unique to the light-exposed samples ($R^2 = 0.96$; $p = 0.004$).

4. DISCUSSION

4.1. Impact of Photodegradation on Plastic Fate. These findings add to the growing body of literature suggesting that photochemical oxidation of plastic to DOC is an important fate of marine plastic. While even the pure PE leaches some DOC in the dark—likely processing impurities, by-products, and oligomers[22]—light exposure consistently produces substantially more DOC (Figure 1b). Moreover, photoproduction of DOC increases linearly with sunlight exposure time (Figure 1c), and radiocarbon measurements demonstrate that the added DOC is plastic-derived (Figure 1d). Although we focused on PE-based plastics, several studies on DOC photoproduction from other polymers (e.g., polystyrene, polypropylene, and PE terephthalate) suggest that our results are relevant to a broader class of plastic materials.[7−11,13−15,24,44] This is because all polymers are susceptible to chain scission and oxidation reactions,[11] the

inorganic additives detected in this study are commonly used in formulations with other polymers,[22] and several other studies using Orbitrap MS reported that multiple polymer types are susceptible to photodissolution.[10,14,15] Thus, the present work and previous research on this topic collectively suggest that photochemical DOC production is an important fate of plastics in the environment.

Exposure of PE standards and consumer products to sunlight generates tens of thousands of water-soluble compounds (i.e., DOC) on timescales of weeks. These photoproducts span wide ranges in composition (i.e., H/C, O/C, molecular weight; Figures 3, S8, S9 and Table S7) and depend on the composition of the plastic being degraded (Figures 1a and 3). While prior work has reported the generation of hundreds of photochemical transformation products from PE degradation over timescales of years,[10] here we reveal that under more environmentally relevant timescales and conditions, this process yields a mixture of photoproducts that is approximately an order-of-magnitude more complex than previously understood. This revelation was likely made possible for two reasons. First, by screening powerful UVC radiation that does not reach Earth's surface and conducting shorter-term incubations (equivalency of weeks vs years), our experimental design likely maximized the buildup of photochemical intermediates that were subsequently characterized using FT-ICR-MS. Second, the 21 T FT-ICR-MS far outweighs the Orbitrap mass spectrometer in resolving power (10−15-fold higher) and mass accuracy (20-fold higher).[19,20] In this study, the mass resolving power using 21 T FT-ICR-MS was 1,300,000 at m/z 400, enabling us to resolve compounds that may otherwise be overlooked. This experimental design provides the community with a viable path forward toward comprehensively characterizing the diverse array of consumer plastic photoproducts released into aquatic ecosystems.

The growing evidence[7−15] that photochemical transformation of plastics is an important transformation process in

surface waters challenges a widely held assumption about the persistence of plastic in the environment. Numerous stakeholders of this environmental issue, including the scientific community, policymakers, industry, media, and the public, assume that sunlight exposure merely physically fragments macroplastics to microplastics, which subsequently persist forever in the environment.[1−5] For example, a recently published set of guidelines for monitoring and assessing plastic litter in the ocean states that: "plastic fragments will have similar structural properties as larger items of the same polymer".[1] Our findings, along with those from the literature,[7,9,10,14,15,45−47] fundamentally challenge this guideline and indicate that sunlight not only aids physical fragmentation of plastic, it chemically alters it, producing a suite of transformation products that no longer resemble the parent material. Therefore, we suggest that these guidelines be updated to accurately reflect the fate of plastic in the sunlit environment.

Many organic compounds once hypothesized to be inert in the environment are now understood to be labile to degradation. Over the past several decades, many supposedly indestructible materials, including lignin,[35,48−51] black carbon,[29,52,53] and asphaltenes,[54] have eventually been found to have an Achilles heel: sunlight. Like plastics, each of these materials is now known to photodegrade into thousands of unique products.[29,35,54] While it is becoming increasingly clear that plastics are not inert in the environment, more work to determine degradation rates (including variations over space and time),[7] effects of environmental factors (e.g., biofouling,[55] wavelength-dependence,[7] residence time in the photic zone, etc.), and transformation products is needed to fully understand the fate of plastics in the environment.

4.2. Influence of Additives on Plastic Photodegradation.

Our findings suggest that consumer plastic formulations vary widely, leading to differences in the amount of plastic converted to DOC by sunlight. Inorganic additives comprise a substantial portion of all consumer PE bags tested, with around one-third of total plastic mass comprised by additives (Figure 1a). This is not unique to single-use plastic bags; consumer plastics are well known to contain a variety of additives,[22,23] with additives accounting for ~7% of plastic production in 2015.[21] It appears that as a result of these composition differences, all consumer PE bags produced more DOC than the pure PE (Figure 1b). Consistent with our observations, previous studies have shown that consumer-relevant formulations degrade faster than their pure analogues.[7,24] Therefore, to determine environmentally relevant photodegradation kinetics and lifetimes of marine plastics, it is critical to study consumer-relevant formulations.

In addition to driving the amount of DOC produced during sunlight exposure, additives also drive the chemical composition of the DOC. While each bag produced unique DOC formulas, the consumer PE bags had more in common with one another than the pure PE (Figures 3, S9 and Table S8). The presence of TiO_2, a common white pigment, especially appeared to drive large similarities between bags containing this additive, which had 68–94% of formulas in common. This likely reflects the different mechanism for TiO_2-catalyzed degradation, which is largely driven by hydroxyl radicals.[42,56] In contrast, photodegradation of pure PE is driven by chain scission reactions, with dissolved oxygen as the primary oxidant.[10,11] The strong inverse relationship between inorganic additives and the average number of oxygen atoms in the

formulas unique to light-exposed samples also suggests that other factors related to the inorganic additives are at play. While the precise mechanism driving this relationship is not clear, particulate inorganic additives are known to alter the plastic's physical properties (e.g., surface area and light scattering) and require coatings and other processing aids to facilitate dispersion within the polymer matrix.[57−60] Many other additives beyond the ones we identified in the bags, including organic ones, have the potential to alter the photodegradation mechanism and, as a result, DOC quantity and quality.[22,24] Future studies conducted under more controlled conditions should constrain the effects of specific additives, inorganic and organic, on photoproduced DOC quantity and quality, including potential synergy and antagonism between additives.

4.3. Implications for Plastics in the Environment.

Our results indicate that pure, unweathered plastics are poor proxies for studying the fate and impacts (e.g., toxicity,[61−63] biogeochemical processes,[25,64−66] and biofouling[55]) of plastics in the environment. We have known for decades that the plastics in the environment are complex mixtures that undergo weathering processes and release micro- and nanoplastics.[67] Here, we demonstrate that plastics are susceptible to photodegradation on timescales relevant to transit times in surface waters (i.e., weeks to months), yielding tens of thousands of unregulated compounds with unconstrained fates and impacts (Figures 2, 3, S8, S9 and Table S7). Moreover, plastic formulation, which varies widely even for the exact same consumer article (Figure 1a), substantially influences the amount and chemical composition of DOC leached from plastic upon exposure to sunlight (Figures 1b and 3). Yet, the plastic sciences discipline continues to rely on pure, unweathered materials in their experimental frameworks.

Using the plastic toxicity literature as an example, we surveyed 78 plastic toxicity studies referenced in three relatively recent and well-cited reviews[61−63] to determine the proportion of studies that considered plastic formulation and environmental weathering. Among the 78 studies we surveyed, only 33% included consumer goods. Of the 13% that compared consumer goods with their pure analogues, all observed differences in toxicity. Only 15% of the 78 toxicity studies incorporated environmental weathering of any kind, and only 6% explicitly studied photodegraded materials. Although data are scarce and our knowledge is based exclusively on pure polymers, the impacts of photochemical weathering appear to be mixed. A couple of studies reported that exposure of plastic to sunlight increased toxicity,[68,69] one reported no major impact,[70] and another reported decreased toxicity.[71] Our collective findings indicate that a comprehensive and accurate understanding of the fate and impacts of marine plastic pollution—a critical step toward establishing evidence-based policies and developing next-generation materials—requires the research community to embrace the diverse formulations and sunlight-driven transformations of plastics in the environment.
